

Unnecessarily Complicated Research Title

John Smith

California, United States

Abstract

Keywords: Science, Publication, Complicated

1. Introduction

- 2 ● Risk and uncertainty
- 3 ● One rule for all?
- 4 ● Impact of life histories
- 5 ● Comparision of constant catch v changing catch based on trends in an
- 6 empirical index.
- 7 ● catch only - need good catch data if you havent got this how can you
- 8 set catch limits

9 Sustainability and risks to non target exploited marine fish stock popu-
10 lations requires both estimates of current stock status, the effects of fishing
11 pressure (catchability and fishing effort) and the effects of management mea-
12 sures on target populations, however these data are often lacking. Subse-
13 quently there is increasing concern and a growing need for the development
14 of innovative approaches so that management of all marine stocks not just
15 those of high commercial value can be included into the Common Fisheries
16 Policy (CFP [1]) framework. Under the CFP management objectives are to
17 recover stocks and to maintain stocks within safe biological limits to levels
18 that can produce Maximum Sustainable Yield (MSY), including by-catch
19 species by 2015 (Implementation Plan adopted at the World Summit on
20 Sustainable Development, Johannesburg in 2002) and no later than 2020.
21 These conservation objectives are currently being achieved by introducing

22 biological target (can fluctuate around targets) and limit (i.e must not be
23 exceeded) reference points e.g. population size (stock biomass) and/or yields
24 (catches) and/or long-term yields and fishing mortality against which the
25 preservation of stocks within such limits are assessed. These targets or limit
26 reference points are often referred to as harvesting strategies which include
27 an operational component called a harvest control rule (HCR) that are based
28 on indicators (e.g. monitoring data or models) of stock status and to prevent
29 overfishing.

30 The International Council for the Exploration of the Sea (ICES) categorises stocks in to classes *data-rich*, (categories 1 and 2) i.e those that have
31 a quantitative assessment based on conventional methods that require large
32 amounts of data that include a long historical time series of catches and
33 sound biological information [2]; or *data-limited* [3](categories 3 and 4) (often
34 called data poor) those without assessment, forecasts and have limited
35 funding for research. For data-rich stocks ICES uses two types of reference
36 points for providing fisheries advice;

- 38 1. Precautionary Approach (PA) reference points (those relating to stock
39 status and exploitation relative to precautionary objectives) and
40 2. MSY reference points (those relating to achieving MSY)

41 In contrast for data limited stocks MSY *proxy* reference points are used
42 to estimate stock status and exploitation. Often many of the methods used
43 to estimate MSY proxy reference points require length based inputs as they
44 are cheap, easy to collect [4] and are related to life history parameters such as
45 fish size, mortality and fecundity as well as fishery selectivity. For example
46 many methods are being developed to estimate MSY, but currently only 4 are
47 approved by ICES, these include, Surplus Production model in Continuous
48 Time (catch based) (SPiCT; [5], Mean Length Z (MLZ; [6]), Length Based
49 Spawner Per Recruit (LBSPR; [7]) and Length Based Indicators (LBI; e.g.
50 [8]). The aforementioned data limited procedures have differing data requirements,
51 intended uses and obviously have their own strengths and weaknesses.

52 To test the performance of candidate management procedures often requires
53 evaluation of alternative hypothesis about the dynamics of the system
54 e.g. population dynamics (life history dynamics such as growth parameters
55 which are an indication of fishery exploitation levels and management) and
56 the behaviour of the fishery (e.g range contraction and density dependence)
57 etc.. Due to the nature of conflicting objectives, stakeholder interests and the

58 uncertainty in the dynamics of the resource and/or the plausibility of alter-
59 native hypotheses can lead to poor decision making and can be problematic
60 when defining management policy.

61 An intense area of work being researched over the last 2 decades is Man-
62 agement Strategy Evaluation (MSE), which focuses on the broader aspects
63 of fishing (the Ecosystem) whereby different management options are tested
64 against a range of objectives (see [9] (i.e. biological, social, economic)). The
65 approach is not to come up with a definitive answer, but to lay-bare the trade
66 offs associated with each management objective, along with identifying and
67 incorporating uncertainties in the evaluation and communicating the results
68 effectively to client groups and decision-makers. MSE is not intended to
69 be complex but to provide a robust framework that account for conflicting
70 poorly defined objectives and uncertainties that have been absent in conven-
71 tional management [9].

72 MSE methods rely on simulation testing to assess the consequences of
73 a range of management options and to evaluate each performance measure
74 across a range of objectives, requiring the use of an operating model (OM)
75 to simulate the actual system (observation model) which are then fed into an
76 management procedure (MP) to provide catch advice. To assess case specific
77 harvest strategies (via simulation) within the MSE, we will implement a man-
78 agement procedure based on a empirical HCR that adjusts yield depending
79 on stock status for a given set of tunable parameters for each of the harvest
80 strategies and to test their robustness to uncertainty. This approach could
81 also help identify similar conditions across species where particular advice
82 rules are likely to work well, and where they perform poorly for a given a set
83 of parameters.

84 Often empirical harvest control rules require extensive exhaustive param-
85 eter searches to tune or optimise 'hyper-parameters' (external parameters to
86 a model) that aren't directly learnt from estimators. This requires a tech-
87 nique known as a grid search that extensively searches for all combinations of
88 all parameters. In contrast, and some what less time consuming alternative
89 and efficient parameter search strategies can be considered for a given range
90 of parameter space and a known distribution. As such a random sample
91 can be obtained and used to perform the different experiments for parameter
92 optimisation.

93 This paper describes a generic method to simulate differing life history pa-
94 rameters for 5 commercially important european fish species (sprat; *Sprattus*
95 *prattus*, ray; *Rajidae*, pollack; *Pollachius pollachius*, turbot; *Psetta max-*

96 *ima* and brill; *Scophthalmus rhombus* and to assess the performance of each
97 empirical HCRs. Assessment is made via a set of utility functions that indicate where the stock is in relation to ICES limit reference points, target
98 reference points and economics. Our approach is to show the benefits and
99 advance management procedures by using an empirical approach for data limited stocks in comparison to a constant catch HCR strategy i.e one where
100 catches are kept constant and low to ensure no lasting damage is done in
101 periods of low stock productivity or whereby the stock is highly variable year
102 on year, therefore the empirical approach can help optimise catch by setting
103 a precautionary TAC.

106 2. Material and Methods

107 2.1. Materials

108 Life history parameters were obtained from Fishbase (<http://www.fishbase.org>)
109 for growth, natural mortality and maturity were used to develop an age-based
110 Operating Model. To do this the parameters were first used to parameterise
111 functional forms for mass (W), proportion mature (Q), natural mortality
112 (M) and fishing mortality (F) at age. These were then used to calculate the
113 spawner (S/R) and yield-per-recruit (Y/R) which were then combined with
114 a stock recruitment relationship [10] to calculate the equilibrium stock size
115 as a function of fishing mortality (F).

116 This analysis allows a variety of reference points such as those based on
117 Maximum Sustainable Yield (MSY), i.e. B_{MSY} the spawning stock biomass
118 (S) and F_{MSY} the fishing mortality that produces MSY at equilibrium to be
119 estimated. Other reference points are $F_{0.1}$ the fishing mortality on the yield
120 per recruit curve where the slope is 10% of that at the origin, a conservative
121 proxy for F_{MSY} ; and F_{Crash} which is the fishing mortality that will drive
122 the stock to extinction since it is equivalent to a R/S greater than the slope
123 at the origin of the stock recruitment relationship, i.e. recruitment can not
124 replace removals for a fishing mortality equal to F_{Crash} .

125 The equilibrium relationships can then be turned into a forward dynamic
126 model and projected forward.

127 A variety of functional forms can be assumed for all of the various processes,
128 i.e. growth, mortality, maturity, the selection pattern of the fisheries
129 and the stock recruitment relationship. Commonly processes such as growth
130 and maturity-at-age are well known while those for natural mortality and the

131 stock recruitment relationship are poorly known [11]. In the later case as-
132 sumptions have to be made and to evaluate the sensitivity of any analysis to
133 those assumptions a variety of scenarios are considered.

134 *2.2. Methods*

135 Individual Growth

136 Growth in length is modelled by the Von Bertalanffy growth equation [12]

$$L = L_\infty(1 - \exp(-k(t - t_0))) \quad (1)$$

137 where k is the rate at which the rate of growth in length declines as
138 length approaches the asymptotic length L_∞ and t_0 is the hypothetical time
139 at which an individual is of zero length.

140 Length is converted to mass using the length-weight relationship

$$W = aL_t^b \quad (2)$$

141 where a is the condition factor and b is the allometric growth coefficient.

142 Maturity-at-age

143 Proportion mature-at-age is modelled by the logistic equation with 2 pa-
144 rameters: age at 50% (a_{50}) and 95% (a_{95}) mature.

$$f(x) = \begin{cases} 0 & \text{if } (a_{50} - x)/a_{95} > 5 \\ a_\infty & \text{if } (a_{50} - x)/a_{95} < -5 \\ \frac{m_\infty}{1.0 + 19.0^{(a_{50}-x)/95}} & \text{otherwise} \end{cases} \quad (3)$$

145 Selection Pattern

146 By default the fishery is assumed to catch mature fish and so the selection
147 pattern is based on the maturity ogive. It is modelled by a double normal
148 curve, however, to allow scenarios to be implemented where older fish are
149 less vulnerable to the fisheries.

150 The double normal has three parameters that describe the age at maxi-
151 mum selection ($a1$), the rate at which the left-hand limb increases (sl) and
152 the right-hand limb decreases (sr) which allows flat topped or domed shaped
153 selection patterns to be chosen, i.e.

$$f(x) = \begin{cases} 0 & \text{if } (a_{50} - x)/a_{95} > 5 \\ a_\infty & \text{if } (a_{50} - x)/a_{95} < -5 \\ \frac{m_\infty}{1.0 + 19.0^{(a_{50}-x)/95}} & \text{otherwise} \end{cases} \quad (4)$$

154 Stock Recruitment Relationship By default a Beverton and Holt stock
 155 recruitment relationship [13] was assumed, This relationship is derived from
 156 a simple density dependent mortality model where the more survivors there
 157 are the higher the mortality. It is assumed that the number of recruits (R)
 158 increases towards an asymptotic level (R_{max}) as egg production increases i.e.

$$R = Sa/(b + S) \quad (5)$$

159 The relationship between stock and recruitment was modelled by a Bev-
 160 erton and Holt stock-recruitment relationship [13] reformulated in terms of
 161 steepness (h), virgin biomass (v) and $S/R_{F=0}$. Where steepness is the propor-
 162 tion of the expected recruitment produced at 20% of virgin biomass relative
 163 to virgin recruitment (R_0). However, there is often insufficient information
 164 to allow its estimation from stock assessment [14] and so by default a value
 165 of 0.8 was assumed. Virgin biomass was set at 1000 Mt to allow comparisons
 166 to be made across scenarios.

$$R = \frac{0.8R_0h}{0.2S/R_{F=0}R_0(1 - h) + (h - 0.2)S} \quad (6)$$

167 S the spawning stock biomass, is the sum of the products of the numbers
 168 of females, N , proportion mature-at-age, Q and their mean fecundity-at-age,
 169 G , which is taken to be proportional to their weight-at-age i.e.

$$S = \sum_{i=0}^p N_i Q_i W_i \quad (7)$$

170 where fecundity-at-age is assumed proportional to biomass and the sex
 171 ratio to be 1:1. Proportion mature is 50% at the age that attains a length of
 172 150, 0% below this age and 100% above.

173 2.2.1. Operating Model

174 Age based Equilibrium Analysis

175 [10], estimated surplus production using an age-based analysis using an
 176 equilibrium analysis that by combining a stock-recruitment relationship, a
 177 spawning-stock-biomass-per-recruit analysis, and a yield-per-recruit analysis.
 178 For any specified rate of fishing mortality, an associated value of spawning
 179 stock biomass (S) per recruit (R) is S/R is defined, based on the assumed
 180 processes for growth, natural mortality and selection pattern-at-age detailed
 181 in the previous sections.

$$S/R = \sum_{i=0}^{p-1} e^{\sum_{j=0}^{i-1} -F_j - M_j} W_i Q_i + e^{\sum_{i=0}^{p-1} -F_i - M_i} \frac{W_p Q_p}{1 - e^{-F_p - M_p}} \quad (8)$$

When the value of S/R obtained is inverted and superimposed on the stock-recruitment function as a slope (R/S), the intersection of this slope with the stock-recruitment function defines an equilibrium level of recruitment. When this value of recruitment is multiplied by the yield per recruit calculated for the same fishing mortality rate, the equilibrium yield associated with the fishing mortality rate emerges [15].

$$Y/R = \sum_{a=r}^{n-1} e^{\sum_{i=r}^{a-1} -F_i - M_i} W_a \frac{F_a}{F_a + M_a} (1 - e^{-F_i - M_i}) + e^{\sum_{i=r}^{n-1} -F_n - M_n} W_n \frac{F_n}{F_n + M_n} \quad (9)$$

The second term is the plus-group, i.e. the summation of all ages from the last age to infinity.

Forward Projection

The stock recruitment relationship and the vectors of weight, natural mortality, maturity and selectivity-at-age allow a forward projection model to be created, which forms the basis of the Operating Model.

$$N_{t,a} = \begin{cases} R_t, & \text{if } a = 0, \\ N_{t-1,a-1} e^{-Z_{t-1,a-1}}, & \text{if } 1 \leq a \leq A-1, \\ N_{t-1,A-1} e^{-Z_{t-1,A-1}} + N_{t-1,A} e^{-Z_{t-1,A}}, & \text{if } a = A, \end{cases} \quad (10)$$

where $N_{t,a}$ is the number of fish of age a at the beginning of year t , R_t is the total number of recruits born in year t . Here, A is the so-called plus group age, which is an aggregated age greater than or equal to the actual age A .

2.2.2. Management Procedure

The management procedure was based on an empirical MP, where an increase in an index of abundance resulted in an increase in the TAC, while a decrease in the index results in a decrease in the TAC. This process is performed via a derivative control rule (D), and is so called as the control signal

203 is derived from the trend in the signal (abundance), i.e. to the derivative of
 204 the error.

$$TAC_{y+1}^1 = TAC_y \times \begin{cases} 1 - k_1 |\lambda|^\gamma & \text{for } \lambda < 0 \\ 1 + k_2 \lambda & \text{for } \lambda \geq 0 \end{cases} \quad (11)$$

205 where λ is the slope in the regression of $\ln I_y$ against year for the most
 206 recent n years and k_1 and k_2 are *gain* parameters and γ actions asymmetry
 207 so that decreases in the index do not result in the same relative change as as
 208 an increase.

209 The TAC is then the average of the last TAC and the value output by
 210 the HCR.

$$TAC_{y+1} = 0.5 \times (TAC_y + C_y^{\text{targ}}) \quad (12)$$

211 2.2.3. Random Search

212 When running an MSE commonly a set of MP scenarios are run to tune
 213 the MP, this requires running the MSE for each OM scenario for a range of
 214 fixed values in the HCR and then choosing the rule that best meets manage-
 215 ment objectives. If there are a lot of parameters to tune then a grid search
 216 may become unfeasible. An alternative is random search [16] as randomly
 217 chosen trials are more efficient for parameter optimisation than trials based
 218 on a grid. The random parameter search is performed where random combi-
 219 nations of hyperparameters k_1 and k_2 are used to find the optimal solutions
 220 for the MSE model in terms of a) safety, (recruitment in relation to virgin
 221 recruitment), b) yield (catch/MSY), c) proportion of years in the kobe green
 222 zone i.e $B/B_{MSY} > 1$ and $F/F_{MSY} < 1$ and d) Average annual variation in
 223 a TAC from one year to the next (expressed as a proportion of the average
 224 annual catch). For instance as the process is random at each iteration its
 225 likely that the whole of the grid space would be covered in the simulation
 226 providing that there are enough iterations, there is a greater chance of finding
 227 the optimal parameter pairs.

228 3. Results

229 Results from our simulated life histories illustrate the diversity in relation
 230 to growth, size and maturity and are presented in Fig.1. These plots show
 231 that for fast growing species which are small in size l_∞ (asymtopic length

232 parameter - maximum attainable length) species such as sprat, the growth
233 parameter k is high. There are also inherent relationships between length at
234 maturity and the maximum attainable length. For instance sprats length-at-
235 50%-maturity l_{50} are low, in contrast to a slower growing larger species l_∞
236 such as ray or pollack.

237 Observations in Fig.2 shows the resulting trends of the vectors from the
238 OM for natural mortality, selectivity, maturity and length in relation to age.
239 Selectivity is derived from maturity and results show that the faster growing
240 species (Fig.1 i.e. sprat) are more selective to fishing, have a high natural
241 mortality at lower ages and thus length. However for the slower growing
242 larger (here represented by length) species (e.g. pollack or ray) have a higher
243 natural mortality rate at lower ages, are more selective/mature with age
244 increases. Interestingly the most significant natural mortality rate increases
245 are associated with turbot at lower ages, however in contrast for the similar
246 flatfish brill, the rate isn't as steep.

247 Fig.3 displays the equilibrium relationships of the OM. Comparisons of
248 reference points estimates can be made across species. The m/k plot shows
249 interesting trends with lower values for sprat where the growth rate k is
250 considerably higher than the natural mortality rate m with little uncertainty
251 around the estimate. In contrast to a slower growing species such as pollack
252 where natural mortality is higher, as is the uncertainty around the estimate.
253 The aforementioned relationships when compared with the proxy for fishing
254 pressure f/m show that the estimate is considerably higher in sprat than
255 pollack.

256 The intrinsic population growth rate r shows that sprats reproductive
257 capacity is higher than all of the species. However the long term average
258 biomass (if fishing at f_{msy}) to deliver MSY b_{msy} is slightly less in comparison
259 to all other species although has a higher MSY and the catch size relative to
260 the stock size f_{msy} is $\gtrsim 1$ thus suggesting overfishing.

275 **4. Discussion**

276 Fisheries management is often faced with multiple conflicting objectives
277 e.g social, biological and economic, and it is widely recognised that their is
278 a need to incorporate these objectives into management plans. However
279 such an experiment on large scale fish stocks is nearly impossible to perform.
280 Therefore performing computer simulations to develop robust management
281 procedures is particularly valuable in data poor situations where knowledge
282 and data are limited, but also in data rich situations as simulation testing an
283 assessment procedure using a model conditioned on the same assumptions is
284 not necessarily a true test of robustness.

285 The main ICES MSY objectives for category 3 and 4 stocks are to max-
286 imise long-term yield, in a manner that is consistent with precautionary prin-
287 ciples; i.e. having a low probability of falling outside biologically sustainable
288 limits. This paper has shown that the desired performance measures can
289 be met via tweaking of the management procedure by adjusting a particular
290 HCR, a specific management objective can be achieved. Here a simplistic
291 utility function was used to evaluate visually how well each HCR performed
292 and the uncertainties associated with the specific combinations.
